The work by Cecilia Laschi was supported by the National University of Singapore through the start-up grant RoboLife and by the Singapore-Italy collaborative project

DESTRO (Grant R23I0IR043). We would like to acknowledge Yujun Huang and Marius Furter from the Zardini Lab at MIT for reviewing the manuscript draft.

Abstract

Soft robots promise inherent safety via their material compliance for seamless interactions with humans or delicate environments. Yet, their development is challenging because it requires integrating materials, geometry, actuation, and autonomy into complex mechatronic systems. Despite progress, the field struggles to balance task-specific performance with broader factors like durability and manufacturability—a difficulty that we find is compounded by traditional sequential design processes with their lack of feedback loops. In this perspective, we review emerging co-design approaches that simultaneously optimize the body and brain, enabling the discovery of unconventional designs highly tailored to the given tasks. We then identify three key shortcomings that limit the broader adoption of such co-design methods within the soft robotics domain. First, many rely on simulation-based evaluations focusing on a single metric, while real-world designs must satisfy diverse criteria. Second, current methods emphasize computational modeling without ensuring feasible realization, risking sim-to-real performance gaps. Third, high computational demands limit the exploration of the complete design space. Finally, we propose a holistic co-design framework that addresses these challenges by incorporating a broader range of design values, integrating real-world prototyping to refine evaluations, and boosting efficiency through surrogate metrics and model-based control strategies. This holistic framework, by simultaneously optimizing functionality, durability, and manufacturability, has the potential to enhance reliability and foster broader acceptance of soft robotics, transforming human-robot interactions.

Keywords: Soft Robotics, Co-Design

1 Introduction

Robots have long been used in industrial tasks requiring precision and strength, such as assembly and manufacturing [1]. However, societal challenges now call for robots designed for human-centered environments like homes and public spaces [2–4]. To operate safely in dynamic, unpredictable settings—and in line with Asimov’s First Law to avoid harming humans [5, 6]—robots should incorporate inherent physical compliance. Modern systems use advanced controls like safety filters, compliant control, real-time collision detection, and predefined safety zones [7], relying on sophisticated sensors and algorithms to preempt hazards [8]. Collaborative robots (cobots) are designed with decoupled actuators, reduced inertia, and compliant controllers for safer human interaction, yet their rigid components can still pose risks [9]. Although collision detection can mitigate danger by slowing or stopping robots near humans [10], it does not completely eliminate injury risk.

Soft robotics offers a transformative approach by embedding safety directly into a robot’s materials and structure, reducing reliance on complex computational algorithms [11, 12]. This inherent compliance enables safe human interaction and operation in sensitive settings such as personal assistance, caregiving, and handling delicate items [13, 14]. However, soft robot development is inherently complex, requiring the seamless integration of materials, geometry, actuation, sensing, compliant continuum dynamics, perception, and control systems. It is notably difficult to predict how morphological changes affect closed-loop motion, as the design space is much larger than for rigid robots, and the capabilities of the autonomy stack and control are inherently limited by the body. For some morphologies with very complex deformations, designing effective proprioception and control systems is even intractable. Consequently, we observe that traditional sequential design processes [15]—which move from conceptual design through mechatronic design to the development of autonomy and control systems—struggle with this complexity, leading to robots that exhibit imprecise, oscillatory motions, limited payload capacity, and inadequate force output [16–20].

Related Work and Limitations

Co-design strategies have proven effective in addressing multi-objective problems and accommodating the compositional, hierarchical nature of complex systems [21]. In this perspective, we review recent studies that have introduced algorithms for simultaneous optimization of soft robot morphology and control systems [22–33]. However, we identify several shortcomings that limit their broader application. First, computationally expensive optimization cycles hinder exploration of the full design space [24], due to high-dimensional discretizations [23, 27–29, 31, 32, 34, 35], inefficient algorithms (e.g., evolutionary ones) [24, 25, 28, 34, 36, 37], costly Reinforcement Learning (RL)-based control training [25, 27, 29, 35], and reliance on intensive simulations for fitness evaluation [23, 27–29, 31, 32, 34, 35]. Second, a narrow focus on easily computable evaluation metrics (e.g., locomotion speed [32], workspace [38]) often neglects other vital design values such as manufacturability [39], safety, cost, ecological impact, usability, and regulatory requirements [30]. Third, the actual realization of the design is rarely [30] factored into the co-design optimization process, which limits the incorporation of insights gained from fabrication, prototyping, and lab/field testing. Similarly, the uncertainty associated with simulation-derived evaluation metrics is seldom considered [24], leading to designs that perform well in simulations but underperform in real-world scenarios. Finally, current co-design methods generally fail to incorporate diverse stakeholder input or account for (all) end-user requirements.

We recognize that parallel yet disconnected efforts exist to address these challenges. For instance, efficient category theory-based algorithms have recently been developed for the co-design of self-driving vehicles, considering diverse design values such as cost, compute requirements, vehicle mass, and power [40–42]. In Machine Learning (ML), there is a strong emphasis on generative models for design generation [43], with recent applications in soft robot co-design [32, 44], enabling optimization in a reduced-order space while recovering the full design description. Furthermore, literature in ML and soft robotics explores how to learn reduced-order dynamic models for efficient model-based controller derivation [45–49] as an alternative to sample-inefficient RL.

Fig. 1 Holistic Co-Design of Soft Robots. The five pillars of holistic co-design are (1) Incorporating comprehensive design requirements and values directly into multi-objective optimization; (2) Efficiently exploring the full design space by melding design priors (e.g., biological inspirations, existing solutions) with computationally efficient co-design routines; (3) Explicitly accounting for design realization (e.g., prototyping and testing) via a probabilistic treatment of evaluation metrics and by formalizing the refinement-vs-realization trade-off—enabling targeted prototyping to reduce metric uncertainty and narrow the sim-to-real gap; (4) Fostering cross-disciplinary collaboration and involving all relevant stakeholders in defining design values and providing iterative feedback; (5) Ensuring audibility to preserve design knowledge and guarantee reproducibility. These pillars are inherently interconnected (see green arrows)—for example, stakeholders and the design team co-define design requirements, certain design values (e.g., HRI) demand evaluation in the real world (i.e., enabled by realization), and both the exploration of the design space and the fulfillment of design requirements remain fully auditable.

Additionally, concepts from nonlinear systems and robotics—such as observability [50], controllability [51], and safety [10, 52]—offer computationally inexpensive metrics to assess design fitness. Finally, a robust body of work in Bayesian optimization [53, 54], RL [55], and co-design [56, 57] has explored incorporating uncertainty in evaluation metrics during optimization and using exploration (i.e., realization) to reduce that uncertainty. The goal of this perspective is to synthesize these related yet isolated research directions into a holistic co-design framework that addresses the shortcomings of existing approaches.

Proposed Framework

This perspective outlines a holistic co-design framework that integrates design components, stakeholder values, design processes, and optimization strategies, addressing key limitations of prior soft robotic co-design approaches through five core advances. First, the framework broadens the range of considered objectives and constraints to include safety, fabrication and operational costs, environmental impact, and regulatory compliance. Second, we introduce enhancements to computational co-design, boosting computational efficiency and allowing for global optimization over the design space. Specifically, this is achieved by (i) sampling from reduced-order design spaces decoded into full morphologies [32]; (ii) co-optimizing reduced-order dynamical models, both physics-based [58] and learned [48, 49, 59–61], to capture task-relevant deformations with minimal complexity; (iii) using fast-to-compute surrogate metrics (e.g., controllability or observability) to guide the optimizer away from poor designs early in the process; and (iv) replacing costly RL training with efficient model-based control methodologies grounded in the same reduced-order models [47, 48]. Third, the framework incorporates purposeful physical prototyping to reduce uncertainty in computational evaluations. By treating co-design probabilistically, it accounts for uncertainties, such as the sim-to-real gap [62], and uses high-fidelity simulation and prototyping across varying Technology Readiness Levels (TRLs) [63] to refine evaluation metric estimates. This enables formal trade-offs between computational “refinement” and physical “realization”, taming the sim-to-real gap discrepancies in performances during the development cycle. Fourth, the integration of structured stakeholder engagement ensures that diverse values and requirements are reflected throughout the design process. Finally, the framework supports reproducibility [64] by maintaining an auditable design trail, which is critical for the deployment of soft robots in real-world contexts.

As illustrated in Fig. 1, this co-design paradigm holds promise for enabling soft robots to take on vital roles in caregiving, education, and other human-centered domains. By ensuring both performance and safety, it can support societal well-being and increase public trust in robotic technologies.

2 The Past and Present Soft Robot Design Process

2.1 Traditional Design Process

We depict the traditional (product) design cycle [15, 65], which is also widely applied within soft robotics, in Fig. 2 (Left). It begins with task specifications and proceeds to a preliminary conceptual design, followed by detailed mechatronic development. The open-loop behavior of the resulting design is verified through simulation, fabrication, and testing on prototypes of various Technology Readiness Levels (TRLs) [63]. Typically, control design and reduced-order modeling occur only after validating a viable soft robotic prototype, enabling verification of closed-loop behavior within laboratory settings. Furthermore, steps (2)–(4) often involve iterative cycles of diverging and converging phases [66]. During the *diverging* phase, new design ideas, concepts, and implementations are generated. Conversely, the *converging* phase evaluates these

Fig. 2 The traditional soft robot design process vs. holistic co-design. *Left:* A traditional sequential design cycle [15] applied to soft robots. This sequential workflow lacks iterative feedback loops, leading to information silos and preventing regular, bidirectional sharing of insights and data across the development team and the relevant stakeholders. *Right:* A holistic co-design framework that complements computational refinement with prototyping across various levels of design readiness - visualized as “onion” layers in this graphic. Solid yellow lines denote the prototyping pathway, while dashed orange arrows illustrate how empirical findings continuously inform and update the estimates $\hat{c}_j$ for the real-world design values c_j .

concepts through simulations or prototype tests to identify, for example, via selection matrices [67], promising designs worthy of further development.

The traditional design cycle has several key deficiencies: (i) Although multiple iterations can theoretically “close the loop” of the design cycle, they are often prohibitively expensive due to cost and complexity, and there is no systematic method to incorporate (performance) insights back into design improvements. Connected, the divergence and convergence cycles often (purposefully) lack feedback as well, as noted by Suh’s design theory arguing for orthogonal requirements [68], limiting the transfer of detailed design and prototyping insights to new solutions—even though iterative approaches have proven to enhance product quality and performance. Thus, feedback should be embedded from the start. (ii) Critical later-stage constraints, such as manufacturability and regulatory compliance (e.g., ISO standards), are frequently overlooked in early design phases. (iii) Sequential workflows among mechatronic, perception, modeling, and control teams create informational silos; for example, modeling engineers typically hand off models to control engineers without adequate feedback, hampering iterative refinement. (iv) The loss of “design history” is a major drawback, as undocumented insights, rationales, and trade-offs make revisiting earlier design stages difficult, especially when key team members leave or change roles.

2.2 First Steps Towards Co-Design of Soft Robots

Given the complexity of soft robots and the limitations of traditional design processes—especially the absence of structured and effective feedback cycles and the isolated design of components—the community has recently begun exploring how co-design algorithms could support soft robot development [23, 25, 27, 29, 30, 32, 69, 70].

2.2.1 Definition of (Computational) Co-Design

The term “*co-design*” highlights several distinctions from traditional design approaches, including a *compositional* and hierarchical nature (i.e., designing all system components, such as body and brain, together [30]), a *collaborative* approach involving all teams and stakeholders, and a *continuous* process of design improvement [21]. Co-design strategies have proven highly effective at solving complex, possibly multi-objective, optimization problems with a well-defined design space, cost function, and equality/inequality constraints. Notable examples stem from the fields of chemistry [71, 72], construction engineering [73], mobility systems [74, 75], autonomous vehicles [21, 40–42], articulated robotics [76, 77].

In the context of soft robots, *co-design* specifically refers to design methods that for soft jointly optimize both the robot’s body (e.g., morphology) and brain (e.g., controller, autonomy stack) to meet specific performance criteria and design values [23, 24, 30]. As detailed in the following subsection, numerous and diverse soft robot co-design approaches exist. However, we contend that they can all be unified under a single formulation. Specifically, we propose that the general definition of co-design given by Zardini *et al.* [21] can be adapted to soft robots by formulating it as a constrained nonlinear optimization problem over a parameterized design x , such that

$$\begin{aligned} \min_x \quad & f(x) \\ \text{s.t.} \quad & g(x) = 0, \quad h(x) \leq 0, \end{aligned}$$

where $f(x) : \mathcal{X} \rightarrow \mathcal{C}$ represents the cost or loss function, and $g(x) : \mathcal{X} \rightarrow \mathbb{R}^{n_{\text{eq}}}$ and $h(x) : \mathcal{X} \rightarrow \mathbb{R}^{n_{\text{ineq}}}$ denote the equality and inequality constraints, respectively. For example, in multi-objective optimization, we can define $f(x) = [c_1^\top(x), \dots, c_{n_{\text{obj}}}^\top(x)]^\top$, with each $f_j(x) = c_j(x)$ for $j = 1, \dots, n_{\text{obj}}$ corresponding to design objectives implemented via the evaluation metrics $c_j(x) : \mathcal{X} \rightarrow \mathcal{C}_j$. These objectives might include task performance, manufacturing and operational costs, or environmental impact. Equality constraints typically capture system dynamics, while inequality constraints ensure physical feasibility (such as non-negative volume, adherence to manufacturing tolerances, or minimum geometric dimensions for manufacturability) and guarantee that the design satisfies essential requirements (like minimum safety levels or regulatory standards). Please note that such (inequality) constraints can also be a function of an evaluation metric $c_j(x)$.

Computational co-design refers to methodologies where the entire design evaluation and optimization process is carried out computationally [35, 78]. In this context, rather than using the actual design value $c_j(x)$, typically an estimated value $\hat{c}_j(x)$, derived, for example, from a simulation of the soft robot design, is employed in the optimization process to circumvent the need to physically prototype and test each design.

2.2.2 Review of Soft Robot Co-Design Approaches

Initial efforts in co-design for soft robots optimize both the body (structure, actuation, sensing) and the controller simultaneously [23, 25, 27, 29, 30, 32, 33, 69, 70]. Building on extensive research in mechanical and geometric design [24], these techniques fall into

three categories: size optimization using predefined geometric parameters (e.g., radii, segment lengths, pneumatic chamber dimensions) [30, 38, 79–84]; shape optimization that incrementally adjusts the parametric surfaces while preserving connectivity [85]; and full topology optimization, which completely rethinks the structure by modifying its fundamental elements [23, 27, 29, 31, 32, 35, 86–90].

A key factor in classifying existing co-design approaches is the derivation of control policies: most methods train learning-based controllers using RL from scratch for every iteration, which creates a significant computational bottleneck in the co-design cycle [25, 27, 29]. Recent advances in differentiable physics-based simulation [91–93] indicate that incorporating real-time gradient-based optimization of neural network-parametrized controllers can substantially reduce the computational overhead associated with iterative design-control loops, thereby enhancing sample efficiency and convergence speed [23, 32]. However, these techniques rely on smooth, end-to-end differentiability, which may fail in the presence of contact or discontinuities, and can be vulnerable to local minima.

Existing co-design approaches face several significant limitations. First, they often concentrate solely on task-centric performance metrics [27, 29, 32] rather than encompassing a broader array of design values and requirements—such as safety and regulatory considerations. Second, these approaches focus exclusively on simulation-based design optimization, overlooking the eventual need to realize the design. This oversight can lead to issues like poor real-world performance due to the sim-to-real gap, lack of manufacturability (for example, voxel-based designs [23, 27–29, 31, 32, 34, 35]), and missed opportunities to incorporate feedback from prototyping and breadboard testing. Third, current co-design algorithms often do not explore the full design space because they are computationally too demanding—stemming from high-dimensional design parameterizations, resource-intensive controller derivation, and the reliance on high-fidelity simulation for performance evaluation, which wastes resources on designs that could have been dismissed earlier through intermediate metrics. Finally, there is often a lack of involvement from a diverse group of stakeholders who can help define design requirements and provide feedback on the evolved designs.

3 The Future: Holistic Co-Design of Soft Robots

Holistic co-design represents a paradigm shift in soft robotics, introducing an integrated, application-driven approach that tightly couples a robot’s physical morphology, control system, and user interaction. In contrast to traditional *sequential* design cycles, it enables concurrent development of all system components, refined iteratively through structured feedback loops.

This framework (Fig. 1) extends beyond existing co-design strategies by (a) embracing a wider set of design values, (b) introducing computational improvements that make global design-space exploration feasible, (c) explicitly accounting for the design’s *realization*, (d) and adopting a probabilistic lens that acknowledges uncertainty in performance metrics, such as those arising from sim-to-real gaps, while mitigating it through targeted prototyping and staged validation.

3.1 Multi-Objective Co-Design: Satisfying Comprehensive Design Requirements and Values

Current co-design approaches for soft robots typically consider only one [23, 26, 27, 32, 34, 84], or at most a few [61], evaluation metrics¹ per task. For locomotion tasks, this often means measuring the velocity achieved or the distance traveled in a fixed time period [23, 27], while in manipulation tasks (e.g., pushing), the focus is on how far an object is moved [32]. However, as soft robots transition from prototypes to commercial products, broader design values become essential. These include manufacturing costs and scalability [19, 30, 94, 95], material availability, operational lifespan, and ecological impacts [96]. Additionally, early integration of regulatory compliance (e.g., FDA or EMA standards for medical robots) into the design optimization process helps prevent costly late-stage modifications, ensuring that resulting designs are robust and market-ready.

3.1.1 Exploiting the Safety vs. Performance Trade-off

Soft robots are widely praised for their “intrinsic safety” and natural compliance [13], often touted as an advantage over rigid manipulators [11, 97, 98]. However, these safety claims remain largely unquantified [14], and in the absence of clear design guidelines, engineers often default to overly compliant materials, treating safety as inversely related to performance and precision. This binary framing is misleading. While softness can improve safety, excessive compliance may degrade control accuracy, reduce payload capacity, and limit force application [16–20]. Crucially, safety in soft robots is not only a function of material properties but also of morphology, control, and perception. The lightweight structure and high degrees of freedom intrinsic to soft robots enable safety through both mechanical and algorithmic means.

Our holistic co-design framework formalizes this trade-off as a multi-objective optimization problem, jointly maximizing safety and performance while enforcing worst-case safety constraints. At runtime, adaptive control strategies further modulate the balance between such objectives. This layered approach relaxes traditional morphological constraints, improves robustness, and supports safe operation even under degraded control, expanding the design space while preserving functional effectiveness in human-centered environments.

3.2 Tractable Exploration of the Entire Design Space: Increasing the Efficiency of Computational Co-Design

One key reason co-design approaches are not yet widely adopted in soft robotics is their computational inefficiency and high cost, which severely restrict the design space that can be explored and diminish the chances of finding the optimal design, thereby reducing their practical utility [24]. We identify three primary sources of computational inefficiency in current methods: (i) they often operate in high-dimensional design spaces—for instance, by discretizing the soft robotic geometry into voxels—which makes it extremely challenging, if not impossible, to locate the global optimum; (ii) the

¹Commonly, such evaluation metrics are also referred to as costs, losses, or negative rewards.

Fig. 3 A Framework for Efficient Computational Co-Design of Soft Robots. We sample reduced-order design parameters x from an initial distribution that can include design priors from biological inspiration [24, 96, 99], known mechanisms, or existing soft robot designs. This design space—either learned or explicitly defined by physical or geometric values (i.e., size optimization)—is translated by a design decoder into a detailed robot body description (such as a 3D mesh with sensor and actuator placements) that provides immediate manufacturability feedback. A reduced-order model is then derived [46, 48, 49, 60] or learned to efficiently assess workspace, open-loop compliance, and embodied intelligence [69, 100, 101], offering inexpensive feedback to the optimizer. Similarly, perception and control systems can be developed using this model (via model-based control [47], MPC [46], or differentiable physics [23, 35]), while observability and controllability are evaluated without costly simulations. Finally, closed-loop simulations (low-fidelity using the reduced-order model or high-fidelity FEM-based [91]) assess integrated performance metrics, which in turn optimize the sampling distribution, decoder, and all relevant system parameters. *References in graphic:* (1): [33], (2): [25], (3): [35], (4): [32], (5): [44], (6): [55], (7): [54], (8): [34], (9): [38], (10): [58], (11): [60], (12): [49], (13): [102], (14): [46], (15): [26], (16): [30], (17): [51], (18): [103], (19): [69], (20): [100], (21): [101], (22) [23], (23): [47].

optimization loop is closed via performance metric(s) obtained from one or multiple closed-loop system simulations, and using high-fidelity simulators makes this evaluation process computationally demanding [23, 28, 29, 32, 35]; (iii) assessing closed-loop performance requires access to a controller. In principle, there are two ways to address this: one can train a controller over a set of different designs [104, 105], though this means the controller may not be optimized for a specific design, so the evaluation might not reflect the true performance achievable with a specialized controller. Alternatively, training a controller tailored to the proposed design can fully exploit its kinematics and dynamics to achieve optimal task performance, but this approach is computationally very intensive—especially when using RL controllers trained from scratch [25, 27, 29, 35], or control policies trained via gradient descent using a differentiable simulation [23, 32, 35]—which often struggle with complex hybrid dynamics such as contact.

Our framework, depicted in Fig. 3, paves the way for significantly more efficient computational co-design of soft robots by introducing four key modifications that address the previously mentioned challenges.

3.2.1 Optimizing in a Reduced-Order Design Space

Direct optimization of soft robots requires parameterizing the design via n_x variables $x \in \mathcal{X}$, with $\mathcal{X} = \mathbb{R}^{n_x}$ forming an n_x -dimensional continuous design space². In soft robot co-design, these parameters encode key aspects such as the spatial geometry, actuator [32], and sensor placements [26, 30], material choices, and other structural traits. Traditionally, two approaches have been used: (1) size optimization, where explicit parameters (e.g., number of segments, radii, segment lengths, materials) are chosen [24, 30, 38, 81–84]; and (2) discretization-based shape/topology optimization³, which partitions the design into 2D/3D voxels or particles [25, 29, 34, 89, 90, 106] labeled as empty, passive, active, or sensorized.

However, traditional methods have notable drawbacks. Manually selected parameters are frequently suboptimal, redundant, or include elements that minimally impact design objectives, complicating the co-design process. In contrast, discretization-based methods create high-dimensional optimization spaces that are computationally expensive to optimize and often produce impractical designs (e.g., violating physical/geometric constraints, infeasible to fabricate in practice).

Recent studies [32, 33, 44] overcome these issues by optimizing within a reduced-order design space and then using a generative decoder to reconstruct the complete design (e.g., a 3D mesh with sensor and actuator placements). In our framework, a design sampler in the reduced-order space and a design decoder work in tandem. We define a probabilistic design policy $\vartheta(x) : \mathcal{X} \rightarrow [0, 1]$ that maps parameters to probabilities. During co-design, reduced-order design parameters $x \sim \vartheta(\cdot)$ are sampled and expanded into a full design $d \in \mathcal{D}$ via the decoder $d = \psi(x)$. The decoder can be model-based (e.g., via parametric CAD) or implemented using learned generative models such as VAEs [33, 44], GANs [107], or Diffusion models [32]. Design priors—derived from proven soft robot examples or bio-inspired concepts [24, 96, 99]—inform the initial distribution, while the optimizer iteratively refines $\vartheta(x)$ [44, 55]. Additionally, sensitivity analysis can reduce the dimensionality of the sampled parameters and improve the decoder’s conditioning [24, 33, 38], enabling the optimizer to focus on critical variables—either by deferring less sensitive parameters via a curriculum approach or by fixing them. This flexible framework supports both model-based and learning-based strategies, rendering the co-design process more computationally tractable without sacrificing the detailed design data needed for accurate evaluation and fabrication.

²While a continuous space is assumed here, discrete design choices can be naturally embedded into this framework.

³Shape optimization adjusts the design boundaries while preserving connectivity, whereas topology optimization can modify connectivity [24].

3.2.2 Co-Optimizing a Control-Oriented Reduced-Order Model

A control-oriented reduced-order model significantly aids in analyzing a system’s motion characteristics—useful for observers, control, and motion planning [46, 48, 49, 58, 60, 102, 108]. While deriving such models is relatively straightforward for rigid manipulators with clearly defined joint-link topologies [77, 109], soft robotics introduces a complex interplay between design, actuation, and tasks (e.g., payload, gravitational forces) that directly influence deformations. This complexity necessitates, in our view, the joint synthesis of morphology and the kinematic model.

Traditionally, the soft robotics community has depended on expert intuition and trial-and-error to establish finite-dimensional descriptions of a robot’s backbone shape (e.g., PCC [110], PCS [111], GVS [112]). However, selecting, deriving, and tuning these first-principles models requires extensive expert knowledge of the system’s deformations and dynamic modes. In the realm of co-design, our focus is on algorithms that automatically identify a suitable, control-oriented, reduced-order model without manual intervention. Promising approaches leverage machine learning to derive data-driven models [46, 102, 113–115], with emerging applications in design optimization [33]. Alternatively, recent methods automatically adapt existing finite-dimensional strain approximations to a given design, addressing sample inefficiency and limited extrapolation [49, 60, 61].

In summary, we contend that co-optimizing both the morphology and the reduced-order model is crucial. Access to such models offers many benefits, including more efficient controller derivation, as detailed in subsequent sections. While some existing methods can automatically derive reduced-order models, they might need to be tailored for effective integration into co-design algorithms.

3.2.3 Surrogate Metrics for Rapid Feedback to the Optimizer

To reduce reliance on performance metrics from resource-intensive closed-loop simulations, we introduce several surrogate metrics that are cheaper to compute. These metrics offer early feedback to the optimizer, enabling the prompt elimination of designs with low predicted fitness. Examples include evaluations of observability and controllability based on the reduced-order model (which directly relates actuator and sensor placement to the structural design), embodied intelligence [69, 100, 101], open-loop compliance [38], safety, and heuristics for manufacturability. In the next paragraph, we detail methods for formulating these controllability and observability metrics.

The controllability and observability of a nonlinear soft robot dynamics model can be assessed using established techniques from nonlinear control theory [50, 51]. Alternatively, one may linearize the system around an equilibrium (e.g., the straight configuration) and analyze the resulting state-space model to evaluate known linear properties. Furthermore, it is crucial to account for closed-loop stability. Research shows that common control strategies like PD+Feedforward are locally stable when guiding the soft robot toward a desired configuration q^d , as long as the potential field is convex (i.e. when $\frac{\partial^2 \mathcal{U}}{\partial q^2} + K_p \succ 0$) [47]. Because we usually strive for low proportional feedback gains to improve phase margins and reduce control effort [116],

achieving broader—or even global—asymptotic stability requires optimizing the soft robot design so that $\frac{\partial^2 \mathcal{U}}{\partial q^2} > 0$ throughout the desired workspace.

3.2.4 Deriving the Controller in a Model-Based Fashion

Finally, we propose leveraging the reduced-order model to derive the control law in a model-based fashion. Recent advancements provide a solid foundation for exploiting dynamical models—whether physics-based or data-driven—for control [47, 117]. For example, using Koopman theory to learn a linear model (or linearizing a nonlinear model around equilibrium) enables the design of optimal controllers in closed form via LQR [108]. For nonlinear models with a physical structure (i.e., with well-defined kinetic and potential energy terms) [48, 49, 58–60], PID+Feedforward [47, 48, 118] or similar closed-form controllers (e.g., PD+ [119], computed torque) can be designed. When dynamics are modeled as generic nonlinear transition functions (e.g., RNNs [113], NODEs [120]), optimal control techniques such as MPC [46] or model-based RL [121] can compute the control input. These model-based approaches to deriving a control law are dramatically more computationally efficient than training an RL control policy from scratch for each design [25, 27, 29, 35].

Fig. 4 Refinement vs. Realization. *Top Left:* This panel shows how refinement affects the design sampling distribution $\vartheta(x)$. Unlike (most) conventional co-design methods that sparsely explore the design space, we condition $\vartheta(x)$ on design priors (e.g., biological inspiration and existing soft robot designs) and iteratively update it via the co-design optimizer until the optimum is reached. *Bottom Left:* Here, we demonstrate how iterative realization refines probabilistic evaluation metrics. Rather than using deterministic metrics that ignore inherent simulation uncertainty, we define a probabilistic distribution $\hat{m}_j(\hat{c}_j, x)$ for each metric, with purposeful prototyping reducing the uncertainty over iterations. *Right:* This panel examines the tradeoff between refinement and realization. We define the realization ratio RealR as the fraction of realization iterations relative to the total iterations and the sim-to-real error as $\|c_j - \mathbb{E}[\hat{c}_j]\|$. We then plot the evolution of real-world cost c_j versus sim-to-real error as iterations increase for a fixed RealR : when $\lim \text{RealR} \rightarrow 0$, designs are optimized computationally with realization occurring only at the end, while $\text{RealR} = 1$ means only the confidence in the evaluation metrics is increased. The optimal ratio RealR^* efficiently minimizes the real-world cost to its optimum $\min_x c_j(x)$ via refinement and reduces the sim-to-real error to zero by updating $\hat{m}_j(\hat{c}_j, x)$ via realization.

3.3 Probabilistic Co-Design Metrics: Explicitly Considering the Refinement vs. Realization Tradeoff

Holistic co-design explicitly accounts for uncertainty when evaluating a design across multiple dimensions [24]. Unlike approaches that use only a few simulation-based metrics [32], we recognize that these indicators are just proxies. For example, although DiffuseBot evaluates tasks like balancing, landing, crawling, gripping, and box manipulation via closed-loop simulation, the well-known sim-to-real gap [62] often causes discrepancies between simulated and actual performance [30]. Additionally, key aspects such as manufacturing costs [30], ecological sustainability, and operational lifetime require prototyping and real-world testing. Thus, the “optimal” design found through computational co-design may not be ideal in practice.

To overcome these challenges, we propose a probabilistic framework that treats evaluation metrics as beliefs about expected performance conditioned on the design specifications. This approach lets us (a) explicitly incorporate metric uncertainty during optimization, (b) optimize using metrics that simulation cannot directly evaluate (e.g., manufacturability), and (c) gradually build confidence through high-fidelity simulations and prototyping. In our framework, designs are iteratively refined based on current probabilistic metric estimates, while prototyping and experimental validation update these estimates—a process we refer to as realization. As illustrated in Fig. 2 (Right), refinement is represented by iterative design cycles in the innermost layer, whereas realization is shown by selected designs moving to the outer layers. This balanced approach, drawing on Bayesian optimization and reinforcement learning, efficiently allocates resources by prioritizing prototyping where predictive confidence is low but real-world performance potential is high.

3.3.1 Definition of Probabilistic Evaluation Metrics

We now formalize the definition of refinement and realization further. As noted earlier, the soft robot co-design problem should be addressed in a multi-objective context where various metrics capture the design values. Now, consider an evaluation metric $c_j = m_j(x)$ that assigns a cost $c_j \in \mathcal{C}_j$ to a design $x \in \mathcal{X}$, which we aim to minimize during the co-design process. Here, the subscript j indicates the j th metric and its associated cost c_j . In practice, however, accurately evaluating these metrics is typically very expensive since it involves building a prototype and conducting extensive field trials or user studies.

Instead, we may have access to a simplified computational model or a current probabilistic belief about the metric, denoted as $\hat{m}_j(\hat{c}_j, x) : \mathcal{C}_j \times \mathcal{X} \rightarrow [0, 1]$, which maps a design x and an estimated cost $\hat{c}_j \in \mathcal{C}_j$ to a probability $\Pr(\hat{c}_j, x)$.

3.3.2 Refinement

During refinement, we adopt a Monte Carlo procedure by querying the metric conditioned on the design, i.e., $\hat{c}_j \sim \hat{m}_j(\cdot, x)$. The resulting estimated cost $\hat{c}_j$ is then employed either as an optimization objective or as part of a constraint. Crucially, the optimizer leverages this estimated cost to update the posterior distribution of the design sampler $x \sim \vartheta(\cdot)$, adjust any free parameters of the decoder $\psi(x)$, and tune

other pertinent parameters such as control or observer gains or hyperparameters of the reduced-order model, as visualized in Fig. 4. This process represents one iteration of computational co-design, which can be visualized as one loop in Fig. 3 and as a cycle within the innermost layer in Fig. 2 (Right). Drawing an analogy to traditional product development cycles, refinement resembles the *diverging* phase, where new concepts and designs are explored and assessed. Moreover, we can draw an analogy with the exploitation stage in RL: assuming the value function $Q(s, a)$ to be fixed, the agent greedily selects actions based on it without further parameter updates. In our case, the role of the value function is played by the estimated evaluation metrics $\hat{m}_j(\hat{c}_j, x)$, and the action policy corresponds to the design sampling distribution $\vartheta(x)$ that capitalizes via computational co-design optimization on the belief encoded in $\hat{m}_j(\hat{c}_j, x)$.

3.3.3 Realization

In realization, our goal is to boost our confidence in the defined metrics. Specifically, we aim to maximize the expected information gain regarding the metrics for the current best design - effectively reducing the posterior entropy (or uncertainty) of the metric around the optimal design, as visualized in Fig. 4. To do this, we can employ methods like Predictive Entropy Search (PES) from Bayesian optimization [53], which assists in pinpointing the global minimizer x^* of the j th cost c_j . The acquisition function $\alpha_{\text{PES}}(x) : \mathcal{X} \rightarrow \mathcal{C}_j$ then enables us to select the next candidate point $x_n = \arg \min_{x \in \mathcal{X}} \alpha_{\text{PES}}(x)$ that most effectively reduces the uncertainty regarding the location of x^* [53], where

$$\alpha_{\text{PES}}(x) = H[\hat{m}_j(x)] - \mathbb{E}_{\hat{m}_j(x^*)} [H(\Pr(\hat{c}_j \mid x, x^*))], \quad (1)$$

and $H[p(x)] = - \int p(x) \log(p(x)) dx$ denotes the differential entropy.

Another challenge in holistic co-design is reducing uncertainty not only for one metric but across all objectives in multi-objective optimization. Future research should develop methods to select the next sample point x_n that minimizes uncertainty over multiple metric estimates $\hat{m}_j(x_n)$, while accounting for the costs, time, and effort needed for accurate ground-truth measurements of the metric.

In holistic co-design, realization parallels the converging stages of traditional product development—using simulations or prototypes to validate designs, mitigate risks, and drive better decision-making. Furthermore, a similar idea to realization exists in reinforcement learning, where exploration involves deliberately sampling previously unvisited state-action pairs [55] to enhance value function estimates. Analogously, we advocate for the use of high-fidelity simulators and prototypes to refine the evaluation metrics of designs that have not yet been realized.

3.3.4 Balancing Refinement vs. Realization

In practice, it is crucial to strike a balance, as visualized in Fig. 4 (Right), between refinement and realization, similar to the exploitation vs. exploration tradeoff in RL. Refinement can generate (potentially) better designs at the cost of computational time, and the resulting design may not be optimal due to uncertainties in the

predicted costs of the various metrics—essentially, a discrepancy between model predictions and reality. In contrast, realization does not directly enhance the design; instead, it bolsters our confidence in the metrics through high-fidelity simulations and prototyping tests at different TRLs, often incurring significant expense, particularly when human designers are involved in fabricating and validating the prototypes. To manage this trade-off, established techniques from reinforcement learning [55] and Bayesian optimization [54] can be applied. For example, one viable approach is to assess the Expected Improvement (EI) [122] when sampling a new design and building its prototype while accounting for the uncertainty inherent in the metric under consideration.

Even when a balance between refinement and realization is achieved, realization—through prototyping and real-world validation—remains both resource- and cost-intensive. To address this challenge, we propose that the community create a shared database where researchers and engineers can contribute soft robotic designs along with their performance benchmarks. In line with efforts to enhance soft robot benchmarking [25, 35] and reproducibility [64], such a repository would improve the initial probabilistic beliefs in the metrics and reduce uncertainty in computational evaluations. Ultimately, this would lessen the reliance on expensive realization processes, which is especially important for aspects like serial production costs that are impractical to repeat multiple times during a given design cycle.

3.4 Synergistic Cross-Disciplinary Collaboration

Collaboration is a key pillar in holistic co-design, involving diverse stakeholders—engineers, end-users, material scientists, and domain experts—from the outset to ensure practical, real-world requirements. For example, designing a robotic harvesting arm benefits from growers’ insights on crop fragility and techniques, guiding the development of soft end-effectors that minimize damage while maximizing yield. Unlike traditional sequential workflows where modeling and control engineers work in isolation, co-design promotes continuous communication and iterative improvement, enabling both roles to work in tandem and refine designs as new insights emerge, ultimately producing a more effective final product.

3.5 Preserving Design Knowledge and Enabling Reproducibility

A major drawback of conventional design is losing the design history, as undocumented decisions vanish with team changes, making it hard to revisit earlier iterations. Holistic co-design overcomes this by maintaining a transparent audit trail of discussions, iterations, and parameter choices, which simplifies design reviews and eases certification. This continuous documentation allows engineers to flexibly adjust designs—whether by refining safety margins, optimizing hardware, or revising software—in response to updated risk analyses and performance data. In doing so, the process aligns technical feasibility and regulatory compliance in an evidence-based, iterative manner.

4 Conclusion and Open Challenges

4.1 Conclusion

In this perspective, we explore achieving high-performing soft robots through co-design. We review current soft robot design and co-design approaches. Existing methods often focus solely on simulation, neglecting key factors such as realization (e.g., prototyping, fabrication), safety, and regulatory considerations. To address these shortcomings, we propose a holistic co-design framework that optimizes broader values (including, e.g., cost, manufacturability, and safety), boosts computational efficiency to enable tractable exploration of the entire design space, and the gaining of confidence in computational evaluation metrics via targeted realization. This framework also allows the formalization of the trade-off between safety and performance, enabling the development of soft robotic designs that perform well in real-world applications while meeting a wide range of design requirements.

4.2 Next Steps and Open Challenges

To achieve holistic co-design of soft robots, we outline the following initial steps for future work: (1) Deriving and verifying model-based metrics—such as manufacturability, fabrication and operation costs, controllability, and observability—that are computationally evaluable and easily combined within co-design methodologies; (2) Incorporating design priors, whether from existing soft robotic designs [84] or biological inspirations [24, 99, 123, 124], into the design sampling process. Generative models (e.g., VLMs trained on large datasets [125, 126]) can propose novel morphologies tailored to the given task [32, 127, 128] and their output could facilitate the sampling of designs in the reduced-order design space via a learned mapping; (3) Using VLMs as design critics [128] to assess environmental impact, feasibility, ergonomics, versatility, and safety and friendliness as perceived by humans; (4) Optimizing the trade-off between design refinement and realization by accounting for the resources required in each cycle, as discussed in Sec. 3.3; (5) Addressing computational challenges in control policy optimization (Sec. 3.2.4) by exploring X-Embodiment policies [129] that enable controllers to work across various soft robotic designs without retraining for each; and (6) Developing a quantitative safety metric for soft robots and subsequently characterizing the Pareto front between safety and performance to structure the trade-off analysis, particularly for tasks such as pick-and-place, where payload, speed, and closed-loop compliance must be optimized simultaneously.
